Interactive proofs were introduced as a generalization of the classical notion of a proof in the hope that more things can be proven in an interactive way (for instance, the non-isomorphism of two graphs). Today we look at a different kind called a probabilistically checkable proof, which is seemingly less general than a classical proof. Again, we start from the definition of NP: A problem $(Y E S, N O)$ is in NP if there is a polynomial-time verifier $V$ and a polynomial $p$ such that

$$
\begin{aligned}
\text { if } x \in Y E S, & \text { then there is a } \pi,|\pi| \leq p(|x|) \text { such that } V(x, \pi)=1 \text {, and } \\
\text { if } x \in N O, & \text { then for all } y,|\pi| \leq p(|x|), V(x, \pi)=0 .
\end{aligned}
$$

Now instead of thinking of $\pi$ as a witness or certificate for $x$, we will think of it as a proof.

## 1 Probabilistically checkable proofs

In the definition of NP, $\pi$ is provided on some tape of the Turing Machine, which $V$ reads from left to right. What happens if instead $V$ has random access to $\pi$, that is, $V$ can provide the value $i$ and observe the $i$ th bit of $\pi$ ? Up to a polynomial factor in the running time, nothing much will change because random access can be simulated easily by sequential access, and vice versa.

We now make the radical restriction that instead of reading the whole proof $\pi, V$ only gets to look at a small portion of $\pi$. If $\pi$ is $m$ bits long the verifier will only get to look at, say, $\log m$ bits within $\pi$. When $V$ is deterministic, this is not terribly interesting: If $V$ gets to see only $\log m$ bits of the proof, then it doesn't need the proof to begin with, because it can try all possible sequences of $2^{O(\log m)}$ values in the locations of the proof it is supposed to read and see if any of those combinations would accept. So a deterministic verifier that has random access to $\log m \operatorname{locations}$ inside the proof is no more powerful than an algorithm running in time polynomial in $m$. Things change substantially when the verifier is randomized. While for any fixing of the randomness, the verifier gets to see only a constant number of bits within $\pi$, as the randomness changes different parts of $\pi$ are exposed.

To model random access to a proof, we view the proof as an oracle. So reading the $i$ th bit from the proof amounts to querying the oracle for its contents at location $i$ and reading off the answer from the answer tape. It turns out that the following two quantities are particularly relevant in this context:

- Randomness complexity: The number of random bits (i.e., the portion of the randomness tape) the verifier uses on an input of length $n$
- Query complexity: The maximum number of locations in the proof the verifier queries on an input of length $n$ (for any setting of the randomness tape)

We are now equipped to give the definition of a probabilistically checkable proof.
Definition 1. A decision problem $(Y E S, N O)$ has a probabilistically checkable proof $(P C P)$ if there exists a polynomial-time randomized non-adaptive oracle Turing Machine $V$ (called the verifier) such that

$$
\begin{aligned}
\text { If } x \in Y E S, & \text { there exists } \pi \text { s.t. } \operatorname{Pr}\left[V^{\pi} \text { accepts } x\right]=1, \\
\text { If } x \in N O, & \text { for all } \pi^{*}, \operatorname{Pr}\left[V^{\pi^{*}} \text { accepts } x\right] \leq 1 / 2
\end{aligned}
$$

By non-adaptive we mean that the verifier $V$ makes all its queries into $\pi$ at once; that is, for every $i$, the location of the $i$ th query cannot depend on the answer to the previous queries.

Notice that there is no restriction of the length of $\pi$. This is because the length is implicitly determined by the randomness complexity and query complexity. Over all possible choices of the randomness, the verifier can access at most $q(n) \cdot 2^{r(n)}$ bits in $\pi$, so this is the effective length of $\pi$.

The most useful setting of parameters is to set the randomness complexity $r(n)$ to $O(\log n)$ and the query complexity $q(n)$ to a constant. The class of decision problems that have such proofs is called PCP. In this setting, the effective length of the proof becomes polynomial in the length of the input, and a randomized verifier can be simulated by a determnistic one that tries all possible choices of the randomness, and accepts iff all of them yield accepting computations. The new verifier works just like a regular NP verifier, thus PCP is contained in NP.

What about the opposite direction? Let's look at an example, say SAT. A PCP for SAT would be a procedure that, on input $\phi$, gets oracle access to a purported (polynomial-length) proof that $\phi$ is satisfiable, gets to examine this proof at a constant number of places, and based on this has to say whether $\phi$ is satisfiable or not. We expect it to be correct most of the time. Can this be possible?

Theorem 2 (The PCP Theorem). NP is contained in PCP.
What this says is that any standard NP proof can be rewritten as a PCP. Formally verifying a mathematical proof is an NP problem: The verifier simply checks that every step is consistent with the rules of logic. If we write this proof in a special PCP form, it is possible to verify its authenticity with confidence, say, $50 \%$ just by looking at a constant number of bits inside the proof. Even this constant is very reasonable: examining 4 locations suffices. If we want to have confidence say $99 \%$ we just repeat the random verification process 7 times.

## 2 Hardness of approximation

Probabilistically checkable proofs for NP are closely related to approximation algorithms for optimization problems in NP. Let's take 3SAT as an example. Suppose you are given a satisfiable 3CNF $\phi$. Since 3SAT is NP-complete, looking for a satisfying assignment of $\phi$ may be asking too much. But suppose you are willing to settle for less; say you are happy with an assignment that satisfies a $99 \%$ fraction of all the clauses. Is there a polynomial-time algorithm for this?

Here is another task which is seemingly even easier. Instead of solving the above approximate search problem which asks you to find a good assignment, now you are only interested in the following promise problem $\varepsilon$-GAP-3SAT:

Input: A boolean formula $\phi$.
Yes instances: $\phi$ is satisfiable.
No instances: Every assignment satisfies fewer than a $(1-\varepsilon)$-fraction of all the clauses in $\phi$.
Clearly if you can find an assignment that satisfies at least $1-\varepsilon$ fraction of the clauses of every satisfiable boolean formula, you can also tell apart yes instances and no instances of $\varepsilon$-GAP-3SAT. But this promise problem is already NP-hard:

Theorem 3. For every $\varepsilon<1 / 8$ there is a polynomial-time reduction from SAT to $\varepsilon$-GAP-3SAT.
Therefore finding an approximate assignment for 3SAT that satisfies $87.6 \%$ of the clauses is as hard as finding one that satisfies all the clauses of a satisifable formula in the worst case. On the other hand, it turns out that there exists an efficient algorithm that satisfies $87.4 \%$ of the clauses.

Proving Håstad's theorem requires several tools which we won't have time to cover. However, if we are settle for a suboptimal value of $\varepsilon$, we will see that Theorem 3 follows easily from the PCP theorem.

### 2.1 Constrant satisfaction problems

To explain the connection between probabilistically checkable proofs and hardness of approximation, it will be convenient to work with a generalization of $q$ SAT ( $q$ CNF satisfiability) called $q \mathrm{CSP}$, for " $q$-ary constraint satisfaction problem." Let $x_{1}, \ldots, x_{n}$ be variables taking values in $\{0,1\}$. A $q$-ary constraint satisfaction problem (over alphabet $\{0,1\}$ ) is a collection of constraints $\phi_{i}:\{0,1\}^{q} \rightarrow$ $\{0,1\}$, each of which is associated with a sequence of $q$ variables $x_{i_{1}}, \ldots, x_{i_{q}}$. So $q$ SAT is a special case of $q \mathrm{CSP}$ where all the constraints are disjunctions of literals; in a $q \mathrm{CSP}$, any constraint in $q$ variables is allowed. The problem of inverting Goldreich's candidate one-way function from Lecture 6 is another example of a constraint satisfaction problem.

The following promise problem GAP-qCSP captures the hardness of finding approximate solutions to $q$-ary constraint satisfaction problems:

Input: A $q$-ary constraint satisfaction problem $\Psi$.
Yes instances: Some assignment satisfies all constraints of $\Psi$.
No instances: Every assignment satisfies at most half of the constraints in $\Psi$.
Here we specialize $\varepsilon$ to $1 / 2$ for convenience. Here is the relation between PCPs and CSPs:
Claim 4. A decision problem has a PCP with randomness complexity $O(\log n)$ and query complexity $q$ on inputs of size $n$ if and only if it reduces in polynomial time to GAP-qCSP.

This connection follows more or less directly from the definitions, but it plays a crucial role in many hardness of approximation proofs.

For the forward direction, assume $(Y E S, N O)$ has a PCP of randomness complexity $O(\log n)$ and query complexity $q$. Then a given instance $z$ of the decision problem reduces to a CSP $\Psi$ with variables $x_{1}, \ldots, x_{n}$ taking value in $\{0,1\}$, where $x_{i}$ represents the contents of the $i$ th location in the proof. For each setting of the randomness $r$ of the verifier there is a constraint $\psi_{r}$ whose variables $x_{r_{1}}, \ldots, x_{r_{q}}$ correspond to those places in the proof queried by the verifier. The constraint $\psi\left(x_{r_{1}}, \ldots, x_{r_{q}}\right)$ takes the value 1 only when the verifier would accept if it would have read the bits $x_{r_{1}}, \ldots, x_{r_{q}}$ from the proof. There are $2^{O(\log n)}=\operatorname{poly}(n)$ such constraints and each of them can be written down in time polynomial in $n$ : To write down the constraint we run the verifier (with a fixed setting of the randomness) on all possible values of the proof bits it depends on and see when it accepts and when it rejects.

If $z$ is a yes instance, then there is some proof $\pi$ that makes $V$ accept regardless of the randomness. Then setting $x_{i}$ to the value of the $i$ th element in $\pi$ will satisfy all the constraints of $\Psi$. If $z$ is a no instance, then no matter what $\pi$ is $V$ rejects at least half the time. Therefore no matter what the variables $x_{i}$ are set to, at least half of the constraints will not be satisfiable.

For the reverse direction, we are given a polynomial-time reduction from ( $Y E S, N O$ ) to GAP-qCSP. Now consider the following PCP verifier $V$ : On input $z$, run the reduction to produce a CSP $\Psi$ over variables $x_{1}, \ldots, x_{n}$. We view the proof $\pi$ as the sequence of values for $\left(x_{1}, \ldots, x_{n}\right)$. The verifier chooses a random constraint $\psi$ of $\Psi$, queries the locations of the proof indexed by the variables in $\psi$, evaluates $\psi$ on the answers, and accepts iff $\psi$ evaluates to 1 . If $z$ is a yes instance then some assignment satisfies all the constraints of $\Psi$ and the corresponding proof will be accepted with
probability 1. If $z$ is a no instance then no assignment satisfies more than half the constraints of $\Psi$, so no matter which proof $x^{*} V$ is provided it is bound to reject at least half the time.

### 2.2 Hardness of approximation for 3SAT

Once we have one problem that is hard to approximate - GAP-qCSP - we can get other ones via reductions.

For example, to show that $\varepsilon$-GAP-3SAT is hard, we can reduce from GAP- $q$ CSP. Given an instance $\Psi$ of GAP- $q$ CSP, we can transform each of its constraints $\psi_{i}\left(x_{i_{1}}, \ldots, x_{i_{q}}\right)$ into a 3CNF formula $\phi_{i}$ by the CSAT to 3SAT reduction from Lecture 5: $\phi_{i}$ has variables $x_{i_{1}}, \ldots, x_{i_{q}}, y_{i 1}, \ldots, y_{i s}, s=O\left(2^{q}\right)$, such that $\left(x_{i_{1}}, \ldots, x_{i_{q}}\right)$ is a satisfying assignment for $\psi_{i}$ if and only if there exists a choice of $y_{i 1}, \ldots, y_{i s}$ so that $\left(x_{i_{1}}, \ldots, x_{i_{q}}, y_{i 1}, \ldots, y_{i s}\right)$ satisfies $\phi_{i}$. The resulting formula has at most $32 \cdot 2^{q}$ clauses.

Now consider the 3CNF instance $\phi$ obtained by taking a conjunction in all the clauses in all such formulas $\phi_{i}$. Clearly if $\Psi$ has a satisfying assignment, it can be extended to a satisfying assignment for $\phi$. We now argue that if no assigmnent satisfies more than half the constraints in $\Psi$, then no assignment can satisfy more than $1-1 / 64 \cdot 2^{q}$ fraction of the clauses in $\phi$.

We prove the contrapositive. Assume there is an assignment that satisfies a $1-\varepsilon$-fraction of constraints in $\phi$, where $\varepsilon=1 / 64 \cdot 2^{q}$. So at most an $\varepsilon$-fraction of the clauses in $\phi$ are not satisfied by this assignment $z$. Since every formula $\phi_{i}$ has $32 \cdot 2^{q}$ clauses, it follows that at most an $2^{q} \cdot \varepsilon \leq 1 / 2$ fraction of the formulas $\phi_{i}$ are not satisfied by the assignment. Now if a formula $\phi_{i}$ is satisfied by $z$, then the corresponding constraint $\psi_{i}$ is also satisfied by the $x$-part of $z$. So more than half of the $\psi_{i}$ are simultaneously satisfiable, and therefore $\Psi$ is not a "no" instance of GAP- $q$ CSP.

To summarize, we gave a polynomial-time reduction from a $q \mathrm{CSP}$ instance $\Psi$ to a $3 \mathrm{CNF} \phi$ such that

> if $\Psi$ is satisfiable, then $\phi$ is satisfiable if $\Psi$ is $\leq 1 / 2$-satisfiable, then $\phi$ is $\leq 1-1 / 64 \cdot 2^{q}$-satisfiable.

Since $q$ is a constant, so is $\varepsilon=1 / 64 \cdot 2^{q}$. By the PCP theorem, we have a polynomial-time reduction from SAT to $\varepsilon$-GAP-3SAT, and so $\varepsilon$-GAP-3SAT is NP-hard.

### 2.3 Hardness of approximation for clique

We now show that assuming the PCP theorem, it is NP-hard to approximate the size of a maximum clique in a graph to within any constant factor. We consider the following promise decision problem $\delta$-CLIQUE:

Input: An undirected graph $G$ on $n$ vertices and a number $k$.
Yes instances: $G$ has a clique of size $k$.
No instances: $G$ does not have a clique of size $\delta k$.
Any potential algorithm that finds a clique of size at least $\delta$ times the size of the maximum clique in $G$ in particular solves $\delta$-CLIQUE: To distinguish yes from no instances simply test if the size of the clique output by the algorithm has size as least $\delta k$.

Theorem 5. $\delta$-CLIQUE is NP-hard for every constant $\delta>0$.

We first reduce from $\varepsilon$-3SAT to $\delta$-CLIQUE for $\delta=1-\varepsilon$ and then show how to make $\delta$ arbitrarily small. This is the same reduction from the proof of Theorem 5 in Lecture 5: This reduction maps satisfiable instances of 3SAT with $m$ clauses into graphs with clique of size $m$. In the other direction, any clique of size $(1-\varepsilon) m$ yields partial assignment that satisfies the corresponding clauses of $\phi$. You will show how to reduce the constant from $1-\varepsilon$ to an arbitrarily small constant $\delta$ in the homework.

## 3 A weak PCP theorem

We now prove the following weak version of the PCP theorem:
Theorem 6. Every NP problem has a PCP with randomness complexity polynomial in the input size and constant query complexity.

This weak PCP theorem will play a role in the proof of the actual PCP theorem which we will see next time. To prove Theorem 6 we need to design a PCP with the required parameters for some NP-complete problem. Instead of working with SAT like we usually do, it will be more convenient to choose another NP-complete problem.

We will start by designing a PCP for a problem in P called LIN. In this problem, the input is a system of linear equations modulo 2 , like

$$
\begin{aligned}
x_{1}+x_{2}+x_{5} & =1 \\
x_{1}+x_{3}+x_{4}+x_{7} & =0 \\
\vdots & \\
x_{2}+x_{7} & =0
\end{aligned}
$$

The problem is to decide if this system of equations has a solution or not.
Let's start with a standard NP proof for LIN. An NP-proof can consist of the values for all the variables $x_{1}, \ldots, x_{n}$. The verifier then checks that these values satisfy all the equations. To read this proof, the verifier needs to observe the values of all $n$ variables, so it must make a total of $n$ queries. The objective is to rewrite the proof in a way that reduces the number of queries to a constant independent of $m$ and $n$.

Here is the first idea. A system of $m$ equations over $n$ variables modulo 2 can be written as $A x=b$, where $A$ is an $m$ by $n$ matrix and $b$ is a column vector of length $n$. (Here the vectors are column vectors.) Now let $r$ be a random vector of length $m$. Consider the products $r^{\mathrm{T}} A x$ and $r^{\mathrm{T}} b$, which are scalar values in $\{0,1\}$. If $A x=b$, then $r^{\mathrm{T}} A x=r^{\mathrm{T}} b$. An easy but important observation is that if at least one of the equations fails to hold, namely $A x \neq b$, then $\operatorname{Pr}\left[r^{\mathrm{T}} A x=r^{\mathrm{T}} b\right]=1 / 2$. To see this, notice that $\operatorname{Pr}\left[r^{\mathrm{T}} A x=r^{\mathrm{T}} b\right]=\operatorname{Pr}\left[r^{\mathrm{T}}(A x-b)=0\right]$. If $A x-b$ is nonzero, then the product $r^{\mathrm{T}}(A x-b)$ has equal chance of being 0 and 1 , so the probability is exactly $1 / 2$.
Once we fix $r$, the expression $r^{\mathrm{T}} A x$ is just some linear combination of the $x_{i}$; so checking that $r^{\mathrm{T}} A x=r^{\mathrm{T}} b$ amounts to verifying that some linear combination of the $x_{i} \mathrm{~S}$ adds to the desired value $r^{\mathrm{T}} b$. In the worst case, however, this expression may involve all the variables $x_{i}$, which take $n$ queries to read, so it seems like we have not made any progress towards verifying the satisfiability of the LIN system with a constant number of queries.

Now comes the second idea. A classical NP-proof for a LIN instance consists of the values for all the variables $x_{1}, \ldots, x_{n}$. In the PCP proof, we will ask not only for the values of the variables, but also for the value of every linear combination of them. This is called the Hadamard encoding of $x$ :
for every $a \in\{0,1\}^{n}$, there is a bit in the proof (indexed by the string $a$ ) which is supposed to give the value of the linear combination $\langle a, x\rangle=a_{1} x_{1}+\cdots+a_{n} x_{n}$. Then, to find out the value $r^{\mathrm{T}} A x$, it is sufficient to query this proof at the location $a=r^{\mathrm{T}} A$ (which is an $n$ bit vector).

So here is the suggested PCP for LIN: On input a LIN system $A x=b$, the verifier expects a proof $\pi \in\{0,1\}^{2^{n}}$, where for every $a \in\{0,1\}^{n}, \pi(a)$ is supposed to equal the value $\langle a, x\rangle$. The verifier chooses a random $r \in\{0,1\}^{m}$, computes $a=r^{\mathrm{T}} A$ and checks that $\pi(a)=r^{\mathrm{T}} b$.
If the system $A x=b$ is satisfiable and $x$ is a satisfying assignment, then the proof $\pi$ where $\pi(a)=\langle a, x\rangle$ clearly makes the verifier accept with probability 1 . Now we want to claim that if the system is not satisfiable, then the verifier rejects with probability at least $1 / 2$.

We can try to reason along the following lines: If $A x \neq b$ for every $x$, then no matter what $x$ is, we have that $r^{\mathrm{T}} A x \neq r^{\mathrm{T}} b$ with probability $1 / 2$. Since $\pi(a)=\langle a, x\rangle=r^{\mathrm{T}} A x$, the verifier rejects with probability $1 / 2$. However, this reasoning is incomplete. What is the problem?

The issue is that the verifier cannot be sure that $\pi(a)=\langle a, x\rangle$ for every proof location $a$; the proof may easily claim, say, that $x_{1}=0, x_{2}=0$, but $x_{1}+x_{2}=1$. If the verifier queries this proof at $x_{1}+x_{2}$, he will not be aware of this inconsistency. So the verifier can be fooled by a proof that "tells it whatever it wants to hear", namely always give a value $\pi\left(r^{\mathrm{T}} A\right)$ that equals $r^{\mathrm{T}} b$.

To take care of this issue, the verifier wants to "force" the proof to be of a particular form: Namely, he wants to be sure that for every $a, \pi(a)=\langle a, x\rangle$ for some assignment $x$. But by our proof of Claim 1 in Lecture 8, to check this condition the verifier needs to query a constant fraction of the whole proof. Our aim is to have the verifier issue a constant number of queries.

What the verifier will be able to do instead is ensure that with high probability, $\pi(a)=\langle a, x\rangle$ for most (say $90 \%$ ) values of $a$. Once this is established, it turns out that the verifier can recover the other $(10 \%)$ of the values, and thus have (with high probability) virtual access to a correct proof of the form $\pi(a)=\langle a, x\rangle$.

### 3.1 The linearity test

Let us reformulate the problem we have to deal with: Given access to a proof $\pi$, which we think of as a string of length $2^{n}$, we want to guarantee (with high probability) that $\pi$ is of the form $\pi(a)=\langle a, x\rangle$ for some $x$ while making only a constant number of (random) queries into $\pi$.

To do this it will be useful to think of $\pi$ not as a proof but as a function of $a$ : This is a function $f$ that maps $\{0,1\}^{n}$ to $\{0,1\}$. We want to check that $f$ is of the form $f(a)=\langle a, x\rangle$ for some $x$; in other words, $f$ should be a linear function over $\mathbb{F}_{2}$, the field of two elements. In this language, we just argued that a verifier of constant query complexity cannot tell apart linear functions from non-linear functions. What the verifier will be able to do, however, is detect if the function is "far" from linear.

Definition 7. A function $f:\{0,1\}^{n} \rightarrow\{0,1\}$ is $\delta$-close to linear if for some $a \in\{0,1\}^{n}, \operatorname{Pr}_{x \sim\{0,1\}^{n}}[f(x) \neq$ $\langle a, x\rangle] \leq \delta$. $f$ is $\delta$-far from linear if it is not $\delta$-close to linear.

Theorem 8. Assume $\delta<1 / 6$. There is an efficient randomized procedure $T^{?}$ which on input $1^{n}$ makes 3 queries into its oracle and

- If $f:\{0,1\}^{n} \rightarrow\{0,1\}$ is linear, then $T^{f}$ accepts with probability 1,
- If $f$ is $\delta$-far from linear, then $T^{f}$ rejects with probability at least $\delta / 2$.

The idea behind the linearity test is extremely simple. A function $f:\{0,1\}^{n} \rightarrow\{0,1\}$ is linear if and only if

$$
f(x)+f(y)=f(x+y)
$$

for every pair $x, y \in\{0,1\}^{n}$. The linearity test will check that this relation is satisfied for a random pair $x, y$.

The linearity test: On input $1^{n}$, choose $x, y \in\{0,1\}^{n}$ independently at random, query the oracle at locations $x, y$ and $x+y$ and accept iff $f(x)+f(y)=f(x+y)$.

Clearly, if $f$ is linear, the test accepts with probability 1 . We need to show that if $f$ is $\delta$-far from linear, then the test rejects with probability at least $\delta / 2$. We will prove the contrapositive, namely

If the test rejects with probability less than $\delta / 2$, then $f$ is $\delta$-close to linear.
So let's assume that the test rejects with probability $<\delta / 2$. We define the function $\ell:\{0,1\}^{n} \rightarrow$ $\{0,1\}$ at $x$ to equal the majority (over $y$ ) of the values $f(x+y)+f(y)$, namely:

$$
\ell(x)= \begin{cases}1, & \text { if } \operatorname{Pr}_{y}[f(x+y)+f(y)=1]>1 / 2 \\ 0, & \text { if } \operatorname{Pr}_{y}[f(x+y)+f(y)=0]>1 / 2\end{cases}
$$

We will now prove that (1) $\ell$ is $\delta$-close to $f$ and (2) $\ell$ is linear.
The first part is straightforward. By assumption, we have that

$$
\operatorname{Pr}_{x, y}[f(x) \neq f(x+y)+f(y)]<\delta / 2
$$

so by Markov's inequality,

$$
\operatorname{Pr}_{x}\left[\operatorname{Pr}_{y}[f(x) \neq f(x+y)+f(y)] \geq 1 / 2\right]<\delta .
$$

Now if $\operatorname{Pr}_{y}[f(x) \neq f(x+y)+f(y)]<1 / 2$, then $\operatorname{Pr}_{y}[f(x)=f(x+y)+f(y)]>1 / 2$ and therefore $\ell(x)=f(x)$, so $\ell$ and $f$ match on a $1-\delta$ fraction of outputs.

For the second part, by the same reasoning as above, we have that

$$
\operatorname{Pr}_{x}\left[\operatorname{Pr}_{y}[f(x) \neq f(x+y)+f(y)] \geq 1 / 4\right]<2 \delta .
$$

Let $S \subseteq\{0,1\}^{n}$ be the set of those $x$ such that

$$
\operatorname{Pr}_{y}[f(x) \neq f(x+y)+f(y)]<1 / 4
$$

Fix a pair of inputs $x, y$ from $S$. We have that

$$
\begin{aligned}
\operatorname{Pr}_{u}[\ell(x) \neq f(x+u)+f(u)]<1 / 4 & \text { since } \ell(x)=f(x) \text { for } x \in S \\
\operatorname{Pr}_{u}[\ell(y) \neq f(y+u)+f(u)]<1 / 4 & \text { since } \ell(y)=f(y) \text { for } y \in S \\
\operatorname{Pr}_{u}[\ell(x+y) \neq f(x+u)+f(y+u)]<1 / 2 & \text { by definition of } \ell
\end{aligned}
$$

Taking a union bound, we have that if $x, y \in S$, then

$$
\operatorname{Pr}_{u}[\ell(x)+\ell(y) \neq \ell(x+y)]<1
$$

Since the quantity inside the probability is independent of $u$, it must hold that $\ell(x)+\ell(y)=\ell(x+y)$ for all $x, y \in S$, so $\ell$ is linear on $S$. It remains to argue that it is also linear when at least one of its inputs falls outside $S$. Let $x, y$ be arbitrary. If for some $u$ all of $u, x+u$, and $y+u$ fall inside $S$ then

$$
\ell(x)+\ell(y)=(\ell(x+u)+\ell(u))+(\ell(y+u)+\ell(u))=\ell(x+u)+\ell(y+u)=\ell(x+y)
$$

On the other hand

$$
\operatorname{Pr}[u, x+u, y+u \text { not all in } S] \leq \operatorname{Pr}[u \notin S]+\operatorname{Pr}[x+u \notin S]+\operatorname{Pr}[y+u \notin S] \leq 6 \delta<1
$$

so there exists a $u$ such that $u, x+u$, and $y+u$ are all in $S$.

### 3.2 A long PCP for LIN

We are now almost ready to describe the PCP for LIN. Let's recall what we did so far: Given a system of equations $A x=b$, we expect a PCP proof of the form $\pi(a)=\langle a, x\rangle$ for all $a \in\{0,1\}^{n}$. The linearity test (repeated a constant number of times) allows us to verify, with probability at least say $9 / 10$, that $\pi$ is $1 / 10$-close to a proof of this form. If we could tell that $\pi$ was exactly of this form, then we can finish by choosing a random linear combination $r$ of the equations in the system, query the proof at location $r^{\mathrm{T}} A$, and accept iff the queried value equals $r^{\mathrm{T}} b$. By our previous reasoning, if $\pi$ encodes a satisfying assignment for the system then the verifier accepts with probability 1 and if it doesn't, it accepts with probability $1 / 2$.

There is one problem left to resolve: The linearity test does not allow us to conclude that $\pi$ is exactly linear, but merely that it is $\delta$-close to linear for a small constant $\delta$ of our choice.

However, it turns out that once we know that $\pi$ is $1 / 20$-close to a linear function $\ell$, we can simulate a query into $\ell$ by making two queries into $\pi$. The idea is simple: To find the value of $\ell(y)$, we choose a random $u$ and output $\pi(y+u)+\pi(u)$. Since both $y+u$ and $u$ are random, with probability $1-2 / 10=4 / 5$ we will have $\pi(y+u)=\ell(y+u)$ and $\pi(u)=\ell(u)$, and therefore $\pi(y+u)+\pi(u)=\ell(y+u)+\ell(u)=\ell(y)$. This procedure which extracts the value of $\ell(y)$ out of $\pi$ (which is a faulty version of $\ell$ ) is called local correction, as it allows us to correct the faults in $y$ locally (i.e. with very few queries).

We can now give the full PCP for LIN: On input $A x+b$ and given oracle access to a proof $\pi$, first run the linearity test a constant number of times to ensure that with probability at least $9 / 10, \pi$ is $1 / 20$-close to a linear function $\ell$. Then choose a random $r$ and compute the value $a=r^{\mathrm{T}} A$. Now to find $\ell(a)$, choose a random $u$ and query $\pi$ at locations $a+u$ and $u$. Accept iff $\pi(a+u)+\pi(u)=r^{\mathrm{T}} b$.
If $A x=b$ has a solution, then the proof $\pi(a)=\langle a, x\rangle$ will pass the linearity test with probability 1 , and $\pi(a+u)+\pi(u)=\langle a, x\rangle$ with probability 1 . Since $\langle a, x\rangle=r^{\mathrm{T}} A x=r^{\mathrm{T}} b$, the verifier accepts with probability one.

If $A x=b$ does not have a solution, let $\ell(a)=\langle a, x\rangle$ be the closest linear function to the proof $\pi$ provided to the verifier. By the analysis of the linearity test, with probability $9 / 10, \pi$ and $\ell$ are $1 / 10$-close. Assume this is the case. Then $r^{\mathrm{T}} A x \neq r^{\mathrm{T}} b$ with probability $1 / 2$. On the other hand, $\ell(a)=\pi(a+u)+\pi(u)$ with probability at least $4 / 5$. All these events hold with probability $1-1 / 10-1 / 2-1 / 5 \geq 1 / 10$; if this is the case, then

$$
\pi(a+u)+\pi(u)=\ell(a)=\langle a, x\rangle=r^{\mathrm{T}} A x \neq r^{\mathrm{T}} b
$$

so the verifier rejects with probability at least $1 / 10$.
To summarize, if $A x=b$ is satisfiable, there exists $\pi$ which makes the verifier accept with probability 1 , and if not, then every $\pi$ makes the verifier reject with probability at least $1 / 10$. We can repeat the PCP a constant number of times to increase the rejection probability to $1 / 2$.

### 3.3 A long PCP for all problems in NP

We now generalize the PCP for LIN into one that works for all of NP. To do so we need an NP-complete problem which looks like LIN. This problem is called QE (for quadratic equations
modulo 2). An instance of QE is a system of homogeneous quadratic equations modulo 2 like

$$
\begin{array}{r}
x_{1} x_{3}+x_{2} x_{2}+x_{5} x_{7}=1 \\
x_{1} x_{1}+x_{1} x_{3}+x_{4} x_{4}+x_{2} x_{7}=0 \\
\vdots \\
x_{2} x_{2}+x_{3} x_{3}=0 .
\end{array}
$$

You can show that this problem is NP-complete by reduction from CSAT, in much the same way we proved that SAT is NP-complete.

Now QE looks a lot like LIN, except that the equations are quadratic. Each of these quadratic equations can be viewed as a linear equation over the $n^{2}$ variables $y_{i j}=x_{i} x_{j}$. The PCP for LIN proves that this system has a solution $y_{i j}$. It remains to verify that the solution is indeed of the form $x_{i} x_{j}$. (For example the solution $y_{11}=y_{22}=0, y_{12}=y_{21}=1$ is not of this form.)

To do so, we augment the proof $\pi$, which represents the Hadamard encoding of $y$ with another part $\rho$ which gives the Hadamard encoding of $x$. Namely, for yes instances, the proof ( $\pi, r h o$ ) will be

$$
\begin{aligned}
\pi(a) & =\sum_{i, j=1}^{n} a_{i j} y_{i j}, \quad \text { where } y_{i j}=x_{i} x_{j} \\
\rho(b) & =\sum_{i=1}^{n} b_{i} x_{i} .
\end{aligned}
$$

Given access to such a $\rho$, the verifier can check that it is, say, $1 / 100$-close to linear. Once it knows that both $\pi$ and $\rho$ are close to linear, it can treat them both as linear by using local decoding, so let's assume that they are both linear. It remains to check that they are consistent.

If $\pi$ and $\rho$ are indeed consistent, then it must be the case that for every $b, c \in\{0,1\}^{n}$ :

$$
\begin{equation*}
\pi\left(b_{1} c_{1}, b_{1} c_{2}, \ldots, b_{n} c_{n}\right)=\rho\left(b_{1}, \ldots, b_{n}\right) \rho\left(c_{1}, \ldots, c_{n}\right) \tag{1}
\end{equation*}
$$

which suggests the following consistency test: Choose $b, c$ at random from $\{0,1\}^{n}$ and check that (1) is satisfied.

Clearly if $\rho$ and $\pi$ are consistent linear functions this test will accept with probability 1 . We now argue that if $\rho$ and $\pi$ are linear but inconsistent then the test will reject with probability at least $1 / 4$. Any two linear functions $\rho$ and $\pi$ have the form

$$
\begin{aligned}
\rho\left(b_{1}, \ldots, b_{n}\right) & =b_{1} x_{1}+\cdots+b_{n} x_{n} \\
\pi\left(a_{11}, \ldots, a_{n n}\right) & =a_{11} y_{11}+a_{12} y_{12}+\cdots+a_{n n} y_{n n}
\end{aligned}
$$

for some $x \in\{0,1\}^{n}, y \in\{0,1\}^{n^{2}}$. Now suppose that $y_{i j} \neq x_{i} x_{j}$ for at least one pair $(i, j)$. Then we claim that with probability at least $1 / 4$,

$$
\rho\left(b_{1}, \ldots, b_{n}\right) \rho\left(c_{1}, \ldots, c_{n}\right) \neq \pi\left(b_{1} c_{1}, b_{1} c_{2}, \ldots, b_{n} c_{n}\right)
$$

To see this, we evaluate both sides:

$$
\begin{aligned}
\rho\left(b_{1}, \ldots, b_{n}\right) \rho\left(c_{1}, \ldots, c_{n}\right) & =\sum_{i, j=1}^{n} b_{i} c_{j} x_{i} x_{j} \\
\pi\left(b_{1} c_{1}, \ldots, b_{n} c_{n}\right) & =\sum_{i, j=1}^{n} b_{i} c_{j} y_{i j}
\end{aligned}
$$

Let's think of the difference of the two: For fixed $x$ and $y$, this is a quadratic polynomial in the variables $b_{i}$ and $c_{j}$. Our assumption is that at least one of the terms $x_{i} x_{j}$ and $y_{i j}$ are different, so this polynomial is not identically zero. But when we evaluate a non-zero quadratic polynomial over $\mathbb{F}_{2}$ at a random input, the probability that it vanishes is at most $1 / 4$. This follows from a more general form of the DeMillo-Lipton-Schwarz-Zippel Theorem from Lecture 5: Write the quadratic polynomial as

$$
\sum_{i=1}^{n} b_{i} \cdot\left(\text { some linear function of } c_{1}, \ldots, c_{n}\right)
$$

Since the polynomial is non-zero, at least one of these linear functions is non-zero, so with probability $1 / 2$ it won't vanish after $c_{1}, \ldots, c_{n}$ are replaced by random values. After this replacement is done, we just get a non-zero linear function in $b_{1}, \ldots, b_{n}$, so with another $1 / 2$ probability this won't vanish after $b_{1}, \ldots, b_{n}$ are replaced by random values.

To summarize, we have the following PCP for QE. The proof is of the form $(\pi, \rho)$, where $\pi$ has length $2^{n^{2}}$ and $\rho$ has length $2^{n}$. We expect $\rho$ and $\pi$ to encode some satisfying assignment $x$ to the system of equations. To check this is the case, we run the following tests say 10 times:

1. Linearity test: Run the linearity test a constant number of times on $\pi$ and $\rho$. This ensures that with probability $99 \%$, both $\pi$ and $\rho$ are $1 \%$-close to linear functions.
2. Consistency test: Choose random $b, c \in\{0,1\}^{n}$ and check that

$$
\tilde{\rho}\left(b_{1}, \ldots, b_{n}\right) \tilde{\rho}\left(c_{1}, \ldots, c_{n}\right)=\tilde{\pi}\left(b_{1} c_{1}, b_{1} c_{2}, \ldots, b_{n} c_{n}\right)
$$

where $\tilde{\rho}(b)=\rho(b+u)+\rho(u)$ for a random $u$, and similarly for $\tilde{\pi}$.
3. Satisfiability test: Choose random $r \in\{0,1\}^{m}$. Take a linear combination of the equations as indexed by $r$ and let $a$ denote the vector of coefficients. Accept if $\tilde{\pi}(a)=r^{\mathrm{T}} b$.

If the QE instance is satisfiable, then $\pi$ and $\rho$ that encode a satisfying assignment make the verifier accept with probability 1 . If not, then no matter what $\pi$ and $\rho$ are, the verifier rejects with constant probability by an extension of the analysis we did for LIN.

## References

The PCP Theorem was proved in 1993 by Arora, Lund, Motwani, Sudan, and Szegedy, who built upon a breakthrough of Arora and Safra from 1992. In 2005 Irit Dinur came up with a completely different proof. Theorem 3 was proved by Håstad. The constant $1 / 8$ in this theorem is optimal; Zwick showed that 1/8-GAP-3SAT can be solved in polynomial time. Much stronger inapproximability results for clique are known; the best one was also obtained by Håstad.
